

# DP Optimizations

1. Convex Hull Trick
2. Divide & Conquer
3. Knuth optimization

# A geometry problem

- Given  $n$  lines:  $y_i = m_i * x + c_i$
- Query: For a given  $x$  (find  $\min(y_i)$ )
- Naive:  $O(NQ)$

# Observation 1: lower envelope

Source of Image: wcipeg

# Construction of lower hull

- Sort lines by decreasing order of slope
- Similar to convex hull, maintain a list/stack of relevant lower hull lines so far and their interval
- Initially add line with interval  $(-\infty, \infty)$

# Construction – part 2

- For each new line  $l_3$  and top 2 stack lines  $l_1$  and  $l_2$  ( $l_2$  is top)
  - If size of stack  $< 2$ ?
    - $X = \text{intersection}(l_2, l_3)$ 
      - If parallel?
- Consider intersection  $x_{old} = \text{intersection}(l_1, l_2)$  and  $x_{new} = \text{intersection}(l_1, l_3)$ 
  - If  $l_1$  and  $l_3$  parallel?
- When should we remove  $l_2$ ?
- After removing all unnecessary lines, add  $(x_{new}, \infty)$

# Answering queries

- At end we will have array of  $(x_1, l_1), (x_2, l_2) \dots (x_m, l_m)$
- $x_1 = -\infty, x_m = \infty, x_1 < x_2 < x_3 \dots < x_m$
- Answering for a particular  $x$ ?
  - Binary search

# Problem #1: CF 319C

- N trees with heights  $a_1, a_2, \dots, a_n$
- $a_1 < a_2 < a_3 < \dots < a_n$
- Cost of cutting one unit of a tree:
  - Recharge after each cut
  - Let k be the maximum fully cut tree (current height  $a_k' = 0$ ) then recharge cost for ONE unit is  $b_k$
  - $b_1 > b_2 > \dots > b_n$
- $a_n = 1, b_n = 0$
- $N \leq 10^5$

# $O(N^2)$ dp solution

- Cut last tree in minimum cost
- Since  $b_n = 0$  all cuts after that are free!
- Let  $dp_i$  = min cost to cut  $i$ th tree
- $dp_i$  = For each  $j < i$  try to cut  $j$  first then cut  $i$ 
  - Cost to cut  $i$  after cutting  $j$  will be  $b_j * a_i$
- Min over  $j$  ( $dp_j + b_j * a_i$ )
- $O(N^2)$ ,  $N = 10^5$  – rekt!

# Observation

- $dp_j + b_j * a_i$
- $y_j = c_j + m_j * x$
- $M_j = b_j, c_j = dp_j$  for  $1 \leq j < i$
- Minimum  $y$  for  $x = a_i$
- Profit!

# Algorithm – $O(N \lg N)$

- $M_j = b_j, c_j = d_j$  for  $1 \leq j < i$
- Minimum  $y$  for  $x = a_i$
- $B_j < b_{j+1}$  – slopes already sorted in required order
- Maintain a deque
  - Stack + array access
- $Dp_1 = b_1$
- Add  $l_1$
- For each  $i$ , calculate minimum value for  $x = a_i$ 
  - Binary search over intervals in the deque
- Then add  $l_i$  ( $m_i = b_i, c_i = d_i$ )
- Note:  $O(N)$  can also be achieved by observing that  $x$  query is always increasing so we can keep a pointer to the last interval and search from there. We have to maintain the pointer when we pop/insert into the stack

# Problem #2: USACO MAR08 acquire

- $N \leq 50000$  rectangles
- “Acquire” all of them.
- Each acquire operation can acquire a subset of rectangles
- Cost of each operation –  $\max\_width * \max\_height$
- Minimum cost?

# Problem continued

- Given  $(w_1, h_1), (w_2, h_2) \dots (w_n, h_n)$
- Cost for an operation:  $\max(w) * \max(h)$  of a subset of rectangles
- How to reduce to convex formulation?
- Hint 1: Two rectangles  $r_1$  and  $r_2$  when will  $r_2$  become irrelevant (i.e. if we acquire  $r_1$  in an operation, we can always acquire  $r_2$  in that operation)
- Hint 2: How would you remove all such irrelevant rectangles

# Solution

- When  $r2.h \leq r1.h$  and  $r2.w \leq r1.w$  then  $r2$  is irrelevant – we can always remove it along with  $r1$
- Sort by  $h$   $r1.h \leq r2.h \leq r3.h \dots \leq r_n.h$
- Maintain a deque of relevant  $r$
- For  $r_i$ , remove from back of deque whenever  $r.w \leq r_i.w$

# Solution – part 2

- At end we will have  $r_1 \dots r_m$  s.t.  $r.h$  is ascending and  $r.w$  is descending
- Each operation is on a contiguous subarray of this.
- $D_{pi}$  = min cost to acquire first  $1..i$  rectangles
- $D_{pi} = \min \text{ over } j < i (dp[j-1] + r_i.h * r_j.w)$
- Familiar?

# D&C - Problem

- Given  $n$  objects with weight  $w_1 \dots w_n$ , divide them into groups of  $m$  contiguous objects
- Weight of a group =  $(\text{sum}(w))^2$
- Minimum cost division
- $N \leq 1000$ ,  $m \leq 1000$
- Sample:  $n = 5$ ,  $m = 3$ 
  - $W = \{1, 1, 2, 3, 1\}$
  - $\text{Sol} = ?$

# D&C – normal dp solution

- Let  $dp[i][j]$  = min cost of dividing first  $i$  objects into  $j$  groups
- $dp[i][j] = \min \text{ over } k < i \text{ of } (dp[k][j-1] + \text{cost}(k+1, i))$ 
  - We try to form a group of objects from  $k + 1$  to  $i$ . The remaining objects will now have to be grouped into  $j-1$  groups ( $dp[k][j-1]$ )
- $\text{cost}(i, j) = (\text{csum}[j] - \text{csum}[i-1])^2$
- Loop over  $j = 1$  to  $m$ :
  - Loop over  $i = 1$  to  $n$ 
    - Loop over  $k = 1$  to  $i - 1$

# D&C – optimal k

- $dp[i][j] = \min \text{ over } k < i \text{ of } (dp[k][j-1] + \text{cost}(k+1, i))$
- Let us store  $opt[i][j] = \text{the optimal } k$
- Key observation:  $opt[i][j] \leq opt[i+1][j]$ 
  - Intuition – since  $\text{cost}(k, i) < \text{cost}(k, i + 1)$  if  $opt[i+1][j]$  is earlier than  $opt[i][j]$  then we could have chosen  $opt[i+1][j]$  for  $dp[i][j]$
- $Opt[.][j]$  is monotonically increasing

# D&C trick

- $\text{Opt}[\cdot][j]$  is monotonically increasing
- For each  $j$  let us calculate  $\text{dp}[\cdot][j]$
- $\text{Compute}(i1, i2, \text{kleft}, \text{kright})$  – calculate  $\text{dp}[i1\dots i2][j]$  given that  $\text{kleft} \leq \text{opt}[i1][j] \leq \text{opt}[i2][j] \leq \text{kright}$
- Initially  $\text{compute}(1, n, 1, n)$

# D&C trick - solution

- `compute(i1, i2, kleft, kright);`
  - Handle small  $i2 - i1$
  - $Mid = (i1 + i2) / 2$
  - Calculate `dp[mid][j]` by normal method but with limits on  $k$ 
    - Loop from `kleft` to `kright`
  - `compute(i1, mid - 1, kleft, opt[mid][j])`
  - `compute(mid + 1, i2, opt[mid][j], kright)`

# D&C time complexity

- Since dividing range( $i_1, i_2$ ) in middle each time - # elements is halved
- Height of recursion tree is  $\log n$
- Each call loops over (kleft to kright)
- The initial range for k (1, n) is split in a single level with each neighbouring ranges sharing 1 endpoint –  $O(n)$  per level
- So calculating  $dp[mid][j]$  takes  $O(n)$  across a level
- There are  $\log n$  level so total  $O(n \lg n)$  for given j
- Overall  $O(mn \lg n)$  down from  $O(m * n^2)$

# Proving monotonicity

- $\text{opt}[i][j] \leq \text{opt}[i+1][j]$

# Knuth opti - Problem

- Given a string we need to split it into various parts
- “abcdefghijk” parts = [3,7]
- “abc”, “defg”, “hijk”
- Cost of splitting a string at any point = length of the string
- Minimum cost of splitting given string at given parts
- $\text{len(string)} \leq 10^5$ ,  $|\text{parts}| \leq 5000$

# Normal solution

- $dp[i][j]$  = min cost of splitting substring  $parts[i]..parts[j]$
- $dp[i][j]$  = split at  $k$ ,  $i \leq k \leq j$ 
  - $dp[i][j] = \min \text{ over } k (dp[i][k] + dp[k][j] + (parts[j+1] - parts[i]))$
  - Since splitting  $(i, j)$  at  $k$  we will have 2 subproblems  $(i, k)$  and  $(k, j)$ . The length of string  $(i, j)$  would be  $parts[j+1] - parts[i]$ . assume  $parts[n+1] = \text{len}(\text{str})$
- $O(n^3)$

# Knuth opti: key observation

- Let  $\text{opt}[i][j]$  be the optimal split
- $\text{opt}[i][j-1] \leq \text{opt}[i][j] \leq \text{opt}[i+1][j]$
- $\text{opt}[i][j-1] \leq \text{opt}[i][j]$ 
  - We are removing back part from  $(i, j)$  so the optimal  $k$  of  $(i, j-1)$  will never be to the right of original one. Because otherwise we could have used that optimal one for  $(i, j)$  itself
- $\text{opt}[i][j] \leq \text{opt}[i+1][j]$ 
  - Same logic as above. We are removing from front. Optimal  $k$  of  $(i+1, j)$  will never be right of optimal  $k$  for  $(i, j)$

# Knuth optimization

- Calculate in increasing order of substring length – calculate for all 1 len substrings  $dp[i][i+1]$
- $S = 0$ :  $dp[1][1]$ ,  $dp[2][2]$ ,  $dp[3][3]$ ...
- $S = 1$ :  $dp[1][2]$ ,  $dp[2][3]$ ,  $dp[3][4]$ ...
- $S = 2$   $dp[1][3]$ ,  $dp[2][4]$ ,  $dp[3][5]$ 
  - Note that when calculating  $dp[2][4]$ , we already have values of  $opt[2][3]$  and  $opt[3][4]$
- $for(s = 0; s \leq n; ++s)$ 
  - $for(i = 1; i + s \leq n; ++i)$ 
    - $J = i + s$
    - Handle  $s \leq 2$
    - $Kleft = opt[i][j-1]$ ,  $kright = opt[i+1][j]$
    - Loop over  $k$  from  $kleft \leq k \leq kright$

# # of operations in inner loop

Calculating ( $n = 8, s = 4$ )	kleft	kright
(1, 5)	O14	O25
(2, 6)	O25	O36
(3, 7)	O36	O47
(4, 8)	O47	8

1. So, for each  $s$ , the  $k$  interval of  $(1, n)$  is split across each starting index.
2. So for each  $s$  the inner loop only takes  $O(n)$  time independent of the second loop for  $i$

# Inner loop

- `for(s = 0; s <= n; ++s)`
  - `for(i = 1; i + s <= n; ++i)`
    - `J = i + s`
    - Handle `s <= 2`
    - `Kleft = opt[i][j-1], kright = opt[i+1][j]`
    - Loop over `k` from `kleft <= k <= kright`
- $O(n^2)$
